Abstract

We investigated the photocatalytic degradation of rhodamine B (RB) dye in the aqueous suspensions of TiO$_2$ (~17 nm) and Ag-deposited TiO$_2$ nanoparticles under visible and UV light irradiation in order to evaluate and distinguish various effects of the Ag deposition on the TiO$_2$ photocatalytic activity. The TiO$_2$ and Ag–TiO$_2$ photocatalysts were characterized by XRD, TEM, XPS, UV-visible absorption and photon correlation spectroscopy. For comparison, the RB photodegradation was carried out in Degussa P25 TiO$_2$ and Ag-deposited P25 suspensions under the same condition. In the RB/Ag–TiO$_2$ system, Ag deposits significantly enhanced the RB photodegradation under visible light irradiation whereas the RB photodegradation under UV irradiation was slightly enhanced. The significant enhancement in the Ag–TiO$_2$ photoactivity under visible light irradiation can be ascribed to simultaneous effects of Ag deposits by both acting as electron traps and enhancing the RB adsorption on the Ag–TiO$_2$ surface.

1. Introduction

Photocatalytic degradation and mineralization of organic and inorganic pollutants on the semiconductor TiO$_2$ have been extensively studied in order to solve environmental problems relating to wastewaters and polluted air [1–8]. Among various metal oxide semiconductors, TiO$_2$ has been the focus of photocatalysts under UV irradiation because of its physical and chemical stability, low cost, ease of availability, non-toxicity, and electronic and optical properties. However, there are still basic problems to be solved for improving the photocatalytic activity of TiO$_2$. Because the semiconductor TiO$_2$ has a high band gap ($E_g > 3.2$ eV), it is excited only by UV light ($\lambda < 388$ nm) to inject electrons into the conduction band and to leave holes in the valence band [9]. Thus, this practically limits the use of sunlight or visible light as an irradiation source in photocatalytic reactions on TiO$_2$ [10]. In addition, the high rate of electron–hole recombination on TiO$_2$ particles results in a low efficiency of photocatalysis [11]. For the purpose of overcoming these limitations of TiO$_2$ as a photocatalyst, numerous studies have been recently performed to enhance electron–hole separation and to extend the absorption range of TiO$_2$ into the visible range. These studies include doping metal ions into the TiO$_2$ lattice [12,13], dye photosensitization on the TiO$_2$ surface [14–18], and deposition of noble metals [19–23].

In particular, noble metal-modified semiconductor nanoparticles become of current importance for maximizing the efficiency of photocatalytic reactions. The noble metals such as Pt [19,20] and Au [21,22] deposited or doped on TiO$_2$ have the high Schottky barriers among the metals and thus act as electron traps, facilitating electron–hole separation and promotes interfacial electron transfer processes [24–27]. Most studies of noble metal-modified TiO$_2$ photocatalysts have focused on the details of the photoinduced electron transfer from the conduction band of UV-irradiated TiO$_2$ to noble metals for improving the photocatalytic activity of TiO$_2$ under UV irradiation. Only a few studies have been reported on visible light-induced photocatalytic reactions using noble metal-modified TiO$_2$ [28,29].

It is expected noble metals deposited on TiO$_2$ may show different effects on the photocatalytic activity depending on the wavelength of light illuminating photoreaction systems because the photocatalytic mechanism under UV irradiation
is generally different from that under visible light irradiation. For example, in the photocatalytic degradation of dye on noble metal-deposited TiO₂ in the presence of O₂, TiO₂ acts as a photosensitizer as well as a photocatalyst under UV irradiation, but a dye acts as a photosensitizer as well as a degraded substrate under visible light irradiation. The charge separation within TiO₂ particles and subsequent electron transfer to O₂ for producing active oxygen radicals (e.g. O₂•−, OOH•, OH•) [15–17] are important to the efficiency of the dye photodegradation under both UV and visible light irradiation. The charge separation and subsequent electron transfer may be enhanced by noble metal deposition on TiO₂ particles, thereby improving the TiO₂ photocatalytic activity under both UV and visible light irradiation. Moreover, surface plasmon resonances of noble metal particles, which can be excited by visible light, increase the electric field around metal particles and thus enhance the surface electron excitation and electron–hole separation on noble metal-deposited TiO₂ particles [30–32]. Consequently, noble metals doped or deposited on TiO₂ are expected to show various effects on the photocatalytic activity of TiO₂ by the different mechanisms as follows that may act separately or simultaneously depending on the photoreaction conditions: noble metals (i) enhance the electron–hole separation by acting as electron traps, (ii) extend the light absorption into the visible range and enhance surface electron excitation by plasmon resonances excited by visible light, and (iii) modify the surface properties of photocatalyst.

Most studies of noble metal deposition on TiO₂ have been focused on group VIII metals using UV-irradiated photodegradation. Besides, some studies have reported contradictory results of the photodegradation of organic molecules on TiO₂ modified by Pt [19,20,33,34] or Ag [23,31] under UV irradiation. This is probably due to the type of TiO₂ used, photoreaction medium, the nature of organic molecules and their redox processes, and the metal content and dispersion [19]. Very few studies have concerned effects of the Ag deposition on the visible light-induced photocatalysis on TiO₂ [35]. Moreover, there has been no report to systematically investigate and distinguish the different roles of Ag deposits in the TiO₂ photocatalytic behavior under UV and visible light irradiation.

In this study, we examined the photocatalytic degradation of the rhodamine B (RB) dye in the aqueous suspensions of TiO₂ and Ag-deposited TiO₂ nanoparticles under visible and UV light irradiation in order to evaluate and distinguish the various effects of Ag deposits on the TiO₂ photocatalytic activity. The TiO₂ nanoparticles (∼17 nm in size) was synthesized by the peptization method, and Ag metals were loaded on TiO₂ by photocatalytic deposition process. The activities of the synthesized TiO₂ and Ag-deposited TiO₂ were also compared to those of the commercial Degussa P25 TiO₂ and Ag-deposited P25 in the same photocatalytic condition. The experimental results are discussed by the different roles of Ag deposits in the RB photodegradation on TiO₂ photocatalyst through different mechanisms under visible and UV light irradiation.

2. Experimental

2.1. Materials

Titanium isopropoxide (+97%) and silver nitrate (AgNO₃, analytical grade) were purchased from Aldrich and used as titanium and silver sources for the preparation of TiO₂ and Ag/TiO₂ photocatalysts. A commercial form of TiO₂ (P25, ca. 80% anatase, 20% rutile; BET area, ca. 50 m²/g; primary size ∼25–30 nm, agglomerate size ∼100 nm) from Degussa was used for the comparison of the photocatalytic activity. Rhodamine B dye (N,N,N′,N′-tetraethylrhodamine, RB) obtained from Junsen was of analytical reagent grade and used without further purification. The structure of RB is shown in Fig. 1. Deionized and doubly distilled water was used for the preparation of all solutions.

2.2. Preparation of TiO₂ and Ag-TiO₂ photocatalysts

The nanoparticulate TiO₂ suspension (denoted as TiO₂ nanosol) was prepared by the peptization method. First, titanium isopropoxide (7.38 ml) was added dropwise to excess water with vigorous stirring at room temperature. The resulting gel was kept stirring for 1 h, and the solvent was then removed by filtration to leave a coagulated TiO₂ powder. In order to peptize the surface of the coagulated TiO₂ [36], the dry powder was added to water (40 ml) with vigorous stirring as adjusting pH to 3 by the addition of HNO₃. The mixture was then heated and aged at 60 °C for 6 h. The obtained TiO₂ nanosol (5 wt.% in TiO₂, pH 3) was transparent and stable for several months. The nanosol was further diluted with water to desired concentrations for the photocatalytic experiments. The TiO₂ concentration was 0.4 wt.% for the RB photodegradation under visible light irradiation and 0.04 wt.% under UV irradiation.

The suspension of metallic silver-deposited TiO₂ nanoparticles (Ag-TiO₂ nanosol) was prepared by a photocatalytic deposition process [37]. A desired volume of aqueous AgNO₃ solution (1.17 × 10⁻² M) was added to the diluted
The mixture solution was then irradiated with UV light (100 W mercury lamp from Philips) for 30 min. The atomic ratio of Ag/Ti was calculated to be in a range of 1–10%.

2.3. Analytical methods

The crystalline phase of the synthesized TiO$_2$ nanoparticles was analyzed by X-ray powder diffraction (XRD) pattern using a Rigaku D/8RAD-C diffractometer with Cu K$_\alpha$ radiation ($\lambda = 1.5418$ nm) at 40 kV and 100 mA. The average particle size of TiO$_2$ in the synthesized nanosol was measured by photon correlation spectroscopy (PCS) with an argon ion laser (Lexel Laser Inc. Model 95-2) operated at 514.4 nm and 200 mW. The TiO$_2$ nanosol was appropriately diluted with water for the light scattering experiment. The light scattered by particles was detected at 90° angle in respect to the incident beam. The optical property of the TiO$_2$ and Ag/TiO$_2$ nanoparticles was studied by UV-Vis absorption spectroscopy using a SCINCO S-2150 spectrophotometer. During the RB photodegradation, the RB concentration was also determined by the absorption spectroscopy. The RB/nanosol was then irradiated with the lamp located above the reactor. The light sources purchased from Philips were a 200 W halogen lamp for visible light and a 100 W mercury lamp for UV. At given irradiation time intervals, a 1 ml-aliquot was taken from the RB/nanosol and analyzed by UV-visible absorption spectroscopy to monitor the degree of the RB photodegradation. The RB concentration was determined from the absorbance at a wavelength of 554 nm ($\lambda_{max}$). To compare the effects of silver deposits, the RB photodegradation was also performed in the commercial Degussa P25 TiO$_2$ and Ag-deposited P25 (Ag-P25) suspensions at the same experimental condition.

3. Results and discussion

3.1. Characterization of TiO$_2$ and Ag-TiO$_2$ photocatalysts

The aqueous TiO$_2$ nanosol synthesized in this experiment was transparent and stable for several months. The crystalline phase of the TiO$_2$ sample was analyzed by XRD, and its XRD pattern is shown in Fig. 2. The TiO$_2$ sample consisted of mainly anatase with minor brookite phase [38] as indicated in the XRD pattern. The particle size of the TiO$_2$ sample was measured by PCS, and its particle size distribution is shown in Fig. 3. The TiO$_2$ sample had an average particle size of 17 nm with a narrow size distribution, indicating the TiO$_2$ nanoparticles were well dispersed in the synthesized nanosol although there were minor aggregates of ca. 50 nm, as can be seen in Fig. 3.

The valence state of silver in the Ag-TiO$_2$ sample was examined by XPS. The XP spectrum in Fig. 4 shows the characteristic Ag 3d$_{5/2}$ peak that has a binding energy of 368 eV with a 6 eV splitting of the 3d doublet [39]. XPS peaks corresponding to Ag$^+$ ion were not found. This result confirms the presence of metallic silver deposits on the TiO$_2$ nanoparticles.
surface of the Ag–TiO$_2$ sample irradiated with UV light. The size of Ag deposits on TiO$_2$ was determined from the TEM image shown in Fig. 5. The size varied with the Ag content in the TiO$_2$ nanosol. For the 2 at.% Ag–TiO$_2$ sample, Ag deposits were well dispersed on the TiO$_2$ particles with an average particle size of 2–4 nm as shown in Fig. 5. At higher silver content, formation of large Ag particles (>100 nm) was observed in the TEM image as similar to the previous report [23]. The Ag content and the particle size of Ag deposits may affect the photocatalytic activity of Ag–TiO$_2$ as discussed in the following section.

3.2. Comparison of photocatalytic activities of TiO$_2$ and Ag–TiO$_2$

3.2.1. RB photodegradation under visible light irradiation

Fig. 6 shows the spectral changes of RB in the TiO$_2$ nanosol under visible light irradiation. A decrease in the absorbance at 552 nm reflects the degradation of RB on the TiO$_2$ photocatalyst, thereby used as a measure of the photocatalytic activity. Compared to the pure TiO$_2$, the Ag–TiO$_2$ nanosol exhibited a significant increase in the RB photodegradation rate as shown in Figs. 7 and 8. It was found that the 2% Ag content was optimum to achieve the highest efficiency of the RB photodegradation for the TiO$_2$

Fig. 4. XP spectrum for UV-irradiated Ag–TiO$_2$ sample.

Fig. 5. TEM micrograph of 2 at.% Ag–TiO$_2$ sample.

Fig. 6. Absorption spectral changes of RB in the TiO$_2$ nanosol as a function of irradiation time (visible light). The initial concentration ($C_0$) of RB was $1 \times 10^{-5}$ M, and the TiO$_2$ content was 0.4 wt.%.

Fig. 7. Photocatalytic degradation of RB in Ag–TiO$_2$ nanosols as a function of the Ag content under visible light (4 h irradiation). The initial concentration ($C_0$) of RB was $1 \times 10^{-5}$ M, and the TiO$_2$ content was 0.4 wt.%.

Fig. 8. Comparison of the RB photodegradation in TiO$_2$, Ag–TiO$_2$, P25, and Ag-P25 nanosols under visible light irradiation. The TiO$_2$ and Ag–TiO$_2$ nanosols were synthesized in this study. Ag-P25 was prepared from the commercial Degussa P25 titania. The initial concentration ($C_0$) of RB was $1 \times 10^{-5}$ M. The TiO$_2$ content was 0.4 wt.%. The Ag content was 2 at.%. 
the large blue shift in $\lambda$ of coworker's results reported by Watanabe et al. [41] and Zhao and particle size ($\sim 17$ nm) of the TiO$_2$ sample as compared to the pure TiO$_2$ (Fig. 8). In addition, the Ag-TiO$_2$ sample showed a higher photodegradation rate than both P25 and Ag-P25, although the pure TiO$_2$ sample had a slightly lower rate than P25 as shown in Fig. 8. By contrast, Ag-P25 exhibited only a 10% increase in the photodegradation as compared to P25. Accordingly, the Ag deposition was more beneficial to the photocatalytic activity of the synthesized TiO$_2$ than to P25 for the visible light-irradiated RB photodegradation. This probably results from a smaller particle size ($\sim 17$ nm) of the TiO$_2$ sample as compared to the pure TiO$_2$ (Fig. 5). The synthesized TiO$_2$ nanosol with smaller particle size and well dispersion is expected to provide a larger surface area for the RB adsorption and Ag dispersion on the TiO$_2$ surface, resulting in the higher photocatalytic activity of the Ag-TiO$_2$ sample as compared to that of Ag-P25.

Under visible light irradiation, the Ag-TiO$_2$ sample showed a 30% increase in the RB photodegradation as compared to the pure TiO$_2$ (Fig. 8). In addition, the Ag-TiO$_2$ sample showed a higher photodegradation rate than both P25 and Ag-P25, although the pure TiO$_2$ sample had a slightly lower rate than P25 as shown in Fig. 8. By contrast, Ag-P25 exhibited only a 10% increase in the photodegradation as compared to P25. Accordingly, the Ag deposition was more beneficial to the photocatalytic activity of the synthesized TiO$_2$ than to P25 for the visible light-irradiated RB photodegradation. This probably results from a smaller particle size ($\sim 17$ nm) of the TiO$_2$ sample as compared to the pure TiO$_2$ (Fig. 5). The synthesized TiO$_2$ nanosol with smaller particle size and well dispersion is expected to provide a larger surface area for the RB adsorption and Ag dispersion on the TiO$_2$ surface, resulting in the higher photocatalytic activity of the Ag-TiO$_2$ sample as compared to that of Ag-P25.

The enhanced adsorption of RB on the Ag-TiO$_2$ surface can be inferred from a blue shift in $\lambda_{\text{max}}$ of the RB absorption spectrum during its photodegradation as shown in Fig. 9. The Ag-TiO$_2$ sample showed a large decrease in the absorbance simultaneously with a large blue shift in $\lambda_{\text{max}}$ during visible light irradiation. According to the previous results reported by Watanabe et al. [41] and Zhao and coworkers [15–17], the blue shift in $\lambda_{\text{max}}$ of RB is caused by de-ethylation of RB occurring in competition with the degradation of the RB chromophore ring under visible light irradiation in CdS or TiO$_2$ suspensions. De-ethylation of RB is mainly a surface occurring reaction, whereas the RB degradation is predominantly a solution bulk process. RB is the $N,N,N',N''$-tetraethylated rhodamine molecule showing $\lambda_{\text{max}}$ at 552 nm. $N,N',N''$-Triethylated rhodamine has $\lambda_{\text{max}}$ at 539 nm, $N,N$'-diethylated rhodamine at 522 nm, and N-ethylated rhodamine at 510 nm [41]. Accordingly, the large blue shift in $\lambda_{\text{max}}$ of RB in the Ag-TiO$_2$ nanosol in Fig. 9(b) results from the significant de-ethylation of RB occurring on the surface of Ag-TiO$_2$ simultaneously with the degradation of the RB chromophore ring during visible light irradiation. This faster de-ethylation of RB on the Ag-TiO$_2$ surface may indicate that RB molecules can be more adsorbed on the Ag-TiO$_2$ surface than the TiO$_2$ surface, since de-ethylation of RB has been reported to be mainly a surface occurring reaction [16].

To compare the adsorption of RB molecules in TiO$_2$ and Ag-TiO$_2$ nanosols, the change in RB absorption spectra was monitored before and after adding the TiO$_2$ and Ag-TiO$_2$ samples to the RB solution in the dark as shown in Fig. 10. The decrease of the RB absorbance in Fig. 10 indicates that RB molecules acting as a photosensitizer under visible light irradiation are more pre-adsorbed on the Ag-TiO$_2$ surface than on the TiO$_2$ surface. About 5.4% of RB molecules were adsorbed on Ag/TiO$_2$ nanoparticles, whereas only 2.5% of RB molecules were adsorbed on TiO$_2$ nanoparticles. Therefore, under visible light irradiation, electron transfer from excited RB molecules to TiO$_2$ particles becomes more efficient in the Ag/TiO$_2$ nanosol, leading to the higher photocatalytic activity of Ag-TiO$_2$. 
3.2.2. RB photodegradation under UV irradiation

Under UV irradiation, only 10% more RB photodegradation was achieved in the Ag–TiO₂ sample as compared to that in the TiO₂ sample (Fig. 11). Ag–P25 also showed 10% enhancement in the RB photodegradation than P25. The Ag–TiO₂ sample still showed a lower photodegradation rate than both P25 and Ag–P25, which is contrary to the result under visible light irradiation. The photocatalytic activities of both TiO₂ and Ag–TiO₂ were significantly lower than that of P25, probably resulting from the lower crystallinity of the TiO₂ sample that was not calcined in this experimental condition. This means that the Ag deposition on the TiO₂ sample does not overcome the lower crystallinity of the TiO₂ sample, thus slightly enhancing the RB photodegradation under UV irradiation.

Consequently, the beneficial effects of Ag deposition on the photocatalytic activity of the TiO₂ sample was more sig-

ificant in the RB photodegradation under visible light irradiation than under UV irradiation, as can be seen in Fig. 12. Also, the Ag deposition was more beneficial to the synthesized TiO₂ sample than to P25 in the RB photodegradation under visible light irradiation (Fig. 9). These results may be ascribed to the different roles of Ag deposits in affecting the photocatalytic behaviors of TiO₂ under UV and visible light irradiation as discussed in the following.

3.3. Roles of Ag nanoparticles deposited on TiO₂

The photocatalytic activity of TiO₂ for the oxidative degradation of RB may be enhanced by the Ag deposition through the following mechanisms:

1. Ag nanoparticles deposited on TiO₂ act as electron traps, enhancing the electron–hole separation and the subsequent transfer of the trapped electron to the adsorbed O₂ acting as an electron acceptor [24–27].

2. More RB molecules are adsorbed on the surface of Ag–TiO₂ than on the TiO₂ surface, enhancing the photoexcited electron transfer from the visible-light sensitized RB to the conduction band of and subsequently increasing the electron transfer to the adsorbed O₂ (Figs. 9 and 10).

3. The surface plasmon resonance of Ag particles is excited by visible light, facilitating the excitation of the surface electron and interfacial electron transfer [30–32].

In addition to these different roles of Ag deposits, the RB photodegradation in aqueous TiO₂ suspension has been shown to follow the different photocatalytic pathways under UV and visible light irradiation as shown in Fig. 13 [16,17,42]. Thus, we can estimate and distinguish various effects of Ag deposits on the TiO₂ photocatalytic activity using the different mechanisms for the roles of Ag deposits and RB photocatalytic degradation.
3.3.1. Effects of Ag nanoparticles under visible light irradiation

The significantly enhanced photodegradation of RB in the Ag–TiO₂ nanosol under visible light irradiation (Fig. 12) may be ascribed to the cooperative roles of Ag deposits according to the three mechanisms mentioned above.

In the self-photosensitization pathway for the RB photodegradation on TiO₂ under visible light irradiation as shown in Fig. 13(a), RB, not TiO₂, is activated into its excited state at λ > 470 nm, injecting an electron into the conduction band (and/or surface states) of the TiO₂ semiconductor, whereas RB is converted to the cationic radical (RB•⁺). In turn, the injected electron on the TiO₂ particle reacts with adsorbed oxidants (usually O₂) to produce reactive oxygen radicals (e.g. O₂•−, •OH, *OH). Subsequently, RB•⁺ is degraded or mineralized by these oxygen radicals. Under visible light irradiation, the semiconductor TiO₂ acts only as an electron-transfer mediator and the oxygen as an electron acceptor leading to an efficient separation of the injected electron and RB•⁺ (acting as a hole).

Also, the rate-determining step in photocatalytic oxidations is believed to be the electron transfer from the TiO₂ surface to the adsorbed O₂ [23,43]. Consequently, the RB adsorption as well as charge separation is essential for the RB photodegradation on TiO₂ under visible light irradiation.

For the RB photodegradation on Ag–TiO₂ under visible light irradiation, the Ag particles on the TiO₂ surface act as electron traps facilitating the electron–hole separation and subsequent electron transfer to the adsorbed O₂ according to the mechanism (1) [24–27].

For the mechanism (2), more RB molecules are adsorbed on the Ag–TiO₂ surface than on the TiO₂ surface, thus leading to more injection of the photoexcited electron from RB•⁺ to the conduction band of TiO₂ in self-photosensitization pathway under visible light irradiation as shown in Fig. 13(a). The enhanced RB adsorption on the Ag–TiO₂ surface can be supported by both the significant blue shift in λₘₐₓ of RB due to faster de-ethylation of RB on Ag–TiO₂ during the RB photodegradation (Fig. 9) and a decrease in the RB absorbance (λₘₐₓ) after contact with Ag–TiO₂ particles in the dark (Fig. 10).

For the mechanism (3), it has been reported that the surface plasmon resonance of Ag metals on TiO₂ is excited by visible light, enhancing the surface electron excitation and electron–hole separation [30–32]. Although we did not obtain the significant absorption band of the plasmon resonance in the Ag–TiO₂ sample due to the low Ag content and scattering of Ag–TiO₂ in this experimental condition, it is expected that the excitation of plasmon resonance may contribute to the enhancement in the photocatalytic activity under visible light irradiation, as reported for Au–TiO₂ [29] and Pt–TiO₂ [28].

In summary, we suggest that the cooperative effects of Ag deposits according to the three mechanisms lead to the significant enhancement in the TiO₂ photocatalytic activity under visible light irradiation as can be seen in Fig. 12.

3.3.2. Effects of Ag particles under UV irradiation

For the RB photodegradation on Ag–TiO₂ under UV irradiation, the Ag deposition slightly increases the TiO₂ photoactivity (Fig. 12). This may be ascribed to the effect of Ag deposits according to only the mechanism (3) under UV irradiation.

In a TiO₂-sensitization pathway for the RB photodegradation under UV irradiation as shown in Fig. 13(b), the valence electrons of TiO₂ particles are excited to the conduction band by UV light and after various other events, electrons on the TiO₂ particle surface are scavenged by the present molecular oxygen to produce reactive oxygen radicals, whereas the valence hole become trapped as the surface-bound O₂•− radicals on oxidation of either the surface OH− group and/or the surface H₂O molecules. Therefore, the charge separation on TiO₂ is a crucial factor to affect the efficiency of the RB photodegradation in TiO₂ under UV irradiation.

For the RB photodegradation on Ag–TiO₂ under UV irradiation, Ag metals act as electron traps according to the mechanism (1) thereby enhancing the charge separation. For the mechanism (2), however, it seems that the enhanced RB adsorption on the Ag/TiO₂ does not significantly contribute to enhancing the TiO₂ photoactivity under UV irradiation as much as under visible light irradiation, since RB molecules are not excited by UV light. Also, the effect of Ag deposits according to the mechanism (2) is not applicable under UV irradiation because the Ag surface plasmon resonance is not present.

Fig. 13. Different photocatalytic pathways for the RB photodegradation on Ag–TiO₂ particles. (a) RB self-photosensitization pathway under visible light irradiation and (b) TiO₂-photosensitization pathway under UV irradiation.
4. Conclusions

We have investigated the different roles of Ag deposits in enhancing the TiO$_2$ photocatalytic activity under UV and visible light irradiation. For comparison, the RB photodegradation was carried out in Degussa P25 titania and Ag-deposited P25 suspensions in the same photoreaction condition. The Ag–TiO$_2$ nanosol showed a 30% increase in the RB photodegradation under visible light irradiation, indicating the enhanced RB adsorption on the Ag–TiO$_2$ surface. Under UV irradiation, however, the Ag/TiO$_2$ sample revealed only 10% more RB photodegradation as compared to the pure TiO$_2$. Under visible light irradiation, the significant enhancement in the Ag–TiO$_2$ photocatalytic activity can be ascribed to simultaneous effects of Ag deposits by both acting as electron traps and enhancing the RB adsorption on the Ag–TiO$_2$ surface. Under UV irradiation, however, Ag deposits may exhibit the effect only as electron traps, thus leading to the slight enhancement in the Ag–TiO$_2$ photocatalytic activity.
